

Heterogeneous Spillovers in Unconditional Cash Transfers

Justin Abraham, Nathaniel Bechhofer, Minki Kim

November 12, 2018

Abstract

In an unconditional cash transfer (UCT) program conducted in rural Kenya, Haushofer and Shapiro (2016) report that villages where households were given transfers saw even those who did not receive transfers obtain spillover benefits, as they can compare non-treated villagers in the treatment villages to those in the control villages. We test if the within-village spillover effects from unconditional cash transfer vary by demographic characteristics. Our findings suggest that even though the spillovers are on average beneficial to those who did not receive the transfer, those who are demographically dissimilar to average villagers might have experienced negative spillovers, both in pecuniary and non-pecuniary measures.

1 Question of interest

Haushofer and Shapiro (2016) demonstrate that villages where villagers were given transfers saw even those who did not receive transfers obtain spillover benefits, as they can compare non-treated villagers in the treatment villages to those in the control villages. We allow for these spillovers to vary by demographics, as we might expect that villagers similar to recipients of the cash transfers would enjoy more spillover benefits.

2 Data

This analysis will use data from a randomized controlled trial of an unconditional cash transfer (UCT) program conducted in rural Kenya (ibid.). Between 2011 and 2013, GiveDirectly provided UCTs to poor households¹ in rural Kenya amounting to USD PPP 404 and USD PPP 1525. The experimental design involved the random assignment of 60 villages to participate in the program and 60 in the control group *and* the random assignment of eligible households within treatment villages to receive a cash transfer. Among households receiving the transfer, the trial also randomized whether the recipient was the head male or female, whether the transfer was paid out regularly or in a lump sum, and the size of the transfer. The data is comprised of a baseline survey collected before the intervention ($N = 1008$), an endline survey a few weeks after the end of the intervention ($N = 940$), and a long-term follow up 3 years after the endline survey ($N = 901$). Surveys collected for sample households information on asset ownership, consumption, education, physical health, subjective well-being, business activity, labor supply, political behavior, investment decisions, and cortisol levels. The baseline and endline survey also collected village-level data on prices, wages, and violent conflict.

3 Empirical Strategy

3.1 Selection among the pure control villages

A potential concern for the estimation strategy we lay out in this section is that in the original experiment the thatched-roof selection criterion was applied to the pure control villages one year after it was applied to households in the treated villages. Thus, pure control households that upgraded their roofs during this one-year span would have been excluded from the sample, allowing for the possibility of selection bias.

We follow the strategy outlined in Haushofer and Shapiro (ibid.) to address this issue by testing whether pure control households differ from the originally sampled

¹At the time eligibility for the program was determined by living in a house with a thatched roof.

households on a set of immutable characteristics.²³

Another concern with the data is that it lacks baseline characteristics for the control villages. Nevertheless, we can still estimate *differences* in spillover effects by exclusively looking at non-treated villagers in the treatment villages and imputing deviations from the endline mean for the control group. This does come with the limitation that we cannot rule out demographic differences in trends that would occur regardless of whether villagers lived in villages that were treated.

3.2 Linear spillover effects

To test whether similarity to treated households results in differential spillover effects, we estimate a parsimonious model that interacts a measure of demographic distance $D_{i,v}$ with an indicator for living in a treatment village S_v .

$$Y_{i,v} = \beta_0 + \beta_1 S_v + \beta_2 D_{i,v} + \beta_3 S_v \times D_{i,v} + \varepsilon_{i,v} \quad (1)$$

$Y_{i,v}$ is the outcome variable of interest with households indexed by i in village v .⁴ $D_{i,v}$ is a measure of distance of each household from characteristics of treatment households. $\varepsilon_{i,v}$ is the idiosyncratic error term. Standard errors are clustered at the village level. We test the null hypothesis $\beta_3 = 0$: that the spillover effect does not depend on distance.

Our first measure of demographic distance uses the pre-treatment levels of each respective outcome and denoted by $Y_{i,v,t=0}$. We calculate a normalized absolute distance from the village-specific average of the treated households.⁵

$$D_{i,v}^{\text{Abs.}} = \frac{|Y_{i,v,t=0} - \bar{Y}_{v,t=0}|}{\text{SD}_v} \quad (2)$$

Additionally, we calculate squared deviations from village averages.

$$D_{i,v}^{\text{Sq.}} = \frac{(Y_{i,v,t=0} - \bar{Y}_{v,t=0})^2}{\text{SD}_v} \quad (3)$$

These specifications assume that only the baseline level of the outcomes moderates the spillover effects of the cash transfers. To allow a more general model that

²These variables are age of the primary respondent, marital status of the primary respondent, highest level of education, the number of children excluding those born between baseline and endline, and the household size at baseline.

³We refer readers to Haushofer and Shapiro (2016) for additional robustness checks including prediction of roof upgrades, treatment effect bounds, and resurveys of the pure control group.

⁴For comparability with the original experiment, we estimate Eq. 1 using the same set of outcome variables: the value of non-land assets, non-durable expenditures, monthly household revenue, and indices of food security, health, education, subjective well-being, and female empowerment. We estimate the eight equations simultaneously to allow for cross-correlations and to be able to conduct joint tests.

⁵As discussed in the previous section, we impute baseline characteristics of the pure control households using their pre-treatment levels.

lets effects differ along multiple observables, we estimate Eq. 1 with a Mahalanobis measure $D_{i,v}^M$. Let \mathbf{X}_i denote the vector of household-level observables and $\bar{\mathbf{X}}$ the village-specific sample means of treated households. $\hat{\mathbf{S}}_v$ is the village-specific covariance. We include the pre-treatment levels of each outcome variable as well as a set of covariates listed in Haushofer and Shapiro (2016).

$$D_{i,v}^M = \sqrt{(\mathbf{X}_i - \bar{\mathbf{X}})' \hat{\mathbf{S}}_v^{-1} (\mathbf{X}_i - \bar{\mathbf{X}})} \quad (4)$$

3.3 Non-linear spillover effects

We further generalize the model by allowing for non-linearities in the distance term.

4 Results

Table 1 reports balance across treatment groups on baseline characteristics of households. As in the original study, we fail to reject a joint test of balance between transfer and spillover households across all of the primary outcomes. Table 2 shows the heterogeneous spillover effects on various dependent variables, using the absolute deviation as a measure of demographic distance. In the first column, we report the effects of one standard deviation increase in absolute distance $D_i^{Abs.}$ on the spillover effects. For all dependent variables, we found evidence of negative relations between demographic distance and spillover effects. The signs of the coefficients for the interaction terms are the opposite of those for the spillover dummy terms.

Table 1: Spillover effects by absolute distance from village means

	Interaction	Treated village	Abs. distance	Control mean (Std. dev.)	Obs.
Value of non-land assets (USD)	-107.11*** (39.30)	95.96*** (32.64)	203.30*** (31.69)	384.05 (298.69)	899
Non-durable expenditure (USD)	-51.67*** (10.78)	34.27*** (9.75)	52.68*** (6.90)	165.38 (90.90)	899
Total revenue, monthly (USD)	-68.45*** (15.78)	48.88*** (9.42)	98.17*** (11.93)	52.66 (95.22)	899
Food security index	0.51*** (0.16)	-0.34*** (0.13)	-0.63*** (0.14)	-0.06 (1.26)	899
Health index	0.04 (0.15)	-0.08 (0.12)	-0.01 (0.12)	0.06 (1.06)	899
Education index	0.20 (0.15)	-0.09 (0.11)	0.04 (0.12)	-0.01 (1.03)	724
Psychological well-being index	0.05 (0.10)	-0.01 (0.10)	0.01 (0.08)	-0.19 (0.94)	1321
Female empowerment index	0.99*** (0.15)	-0.58*** (0.12)	-0.92*** (0.11)	-0.21 (1.15)	621

Notes: The unit of observation is the household for all outcome variables except for the psychological variables index, where it is the individual. The sample is restricted to co-habiting couples for the female empowerment index, and households with school-age children for the education index. All columns include village-level fixed effects, control for baseline outcomes, and cluster standard errors at the village level. * denotes significance at 10 pct., ** at 5 pct., and *** at 1 pct. level.

For all five dependent variables with statistically significant baseline spillover effects, the effects of one standard deviation increase in the absolute distance were more than enough to completely offset the baseline spillover effects. For instance, households one standard deviation away from the mean demographic characteristic of the village they belong to experienced (on average) a *negative* spillover effects on total revenue, which amount to -19.5 USD. We found no significant heterogenous spillover effects on food security, health, and education indices.

In Table 3 we report the results from the same regressions, this time with the squared distances $D_i^{Sq.}$ as a measure of demographic distance. Once again, the results strongly indicate that households dissimilar from an average villager experienced weaker spillover effects. The magnitude of the coefficients of the interaction terms are smaller, because the squared distance measure weights distances far away from the mean more heavily.

Table 2: Spillover effects by squared distance from village means

	Interaction	Treated village	Sq. distance	Control mean (Std. dev.)	Obs.
Value of non-land assets (USD)	-0.47*** (0.05)	103.31*** (20.32)	0.55*** (0.04)	384.05 (298.69)	899
Non-durable expenditure (USD)	-0.44*** (0.03)	22.39*** (7.27)	0.47*** (0.02)	165.38 (90.90)	899
Total revenue, monthly (USD)	-0.48*** (0.02)	25.03*** (4.64)	0.50*** (0.02)	52.66 (95.22)	899
Food security index	0.33*** (0.05)	-0.29*** (0.09)	-0.42*** (0.03)	-0.06 (1.26)	899

5 Conclusion

We tested if within-village spillover effects from unconditional cash transfer vary by demographic characteristics. In an unconditional cash transfer (UCT) program conducted in rural Kenya, Haushofer and Shapiro (2016) found out that villages where villagers were given transfers saw even those who did not receive transfers obtain spillover benefits, as they can compare non-treated villagers in the treatment villages to those in the control villages. Our findings suggest that even though the spillovers are on average positive, those who are demographically dissimilar to other villagers might have experienced negative spillovers, both in pecuniary and non-pecuniary measures.
